1 Mathematical formalism

1.1 Models of synapses

We make the following assumptions:

- There are N identical synapses with M internal functional states.
- The states of different synapses are independent of each other.
- The synapses that are eligible for plasticity are chosen randomly.
- Candidate potentiating/depressing plasticity event timings are distributed as Poisson processes with rates $r^{\text{pot/dep}}$.
- Potentiation and depression are described by Markov processes with transition probabilities $\mathbf{M}^{\text{pot/dep}}$.
- The synaptic weights of the internal states are given by the column vector \mathbf{w} . This can only take values in a finite range that we can shift to ± 1 . Most of the models will only use the two extreme values.

In practice, the overall rate of candidate plasticity events will only set the timescale, and only the relative rates will matter. With this in mind, we define

$$r = r^{\text{pot}} + r^{\text{dep}}, \quad f^{\text{pot}} = \frac{r^{\text{pot}}}{r}, \quad f^{\text{dep}} = \frac{r^{\text{dep}}}{r}. \quad (1)$$

The quantities $f^{\text{pot/dep}}$ measure the fraction of candidate plasticity events that are potentiating/depressing.

The independence and identicalness of synapses means that the state of the system can be completely described by the probability distribution of the internal states, the row vector $\mathbf{p}(t)$.

The evolution of this probability is described by a continuous time Markov matrix matrix, \mathbf{W}^{F} :

$$\frac{d\mathbf{p}(t)}{dt} = r\mathbf{p}(t)\mathbf{W}^{\text{F}}, \quad \mathbf{W}^{\text{F}} = f^{\text{pot}}\mathbf{M}^{\text{pot}} + f^{\text{dep}}\mathbf{M}^{\text{dep}} - \mathbf{I}, \quad (2)$$

where \mathbf{I} is the identity matrix. Eventually, this will settle into the equilibrium distribution:

$$\mathbf{p}^{\infty}\mathbf{W}^{\text{F}} = 0. \quad (3)$$

For models with only two possible synaptic weights, the distribution of synaptic weights is completely described by the mean, $\mathbf{p}(t)\mathbf{w}$.

The $D^bK^{b-/-}$ mice have a lower threshold for depression. We can model this by changing \mathbf{M}_{WT}^{dep} to \mathbf{M}_{MHC}^{dep} , which should have larger off-diagonal matrix elements.

We will look at several different models, the serial model (see [1] and Figure 1a) which has only two values for the synaptic weight, the two-state model (which can be thought of as a special case of the serial model, see Figure 1b), the multistate model (see [2, 3] and Figure 1c) which has a linearly varying synaptic weight, and the cascade model (see [4] and Figure 1d). We will also look at a new, pooled resource model that we will define below in §1.1.1 and a non-uniform version of the multistate model that we will describe in §1.1.2.

For the serial, multistate and two state models, we will use the same value for the transition probabilities, q , for potentiation and depression in the wild-type as well as potentiation in the $D^bK^{b-/-}$ mice. We will use a larger value for q for depression in the $D^bK^{b-/-}$ mice.

For the cascade model, we will use the same value for the parameter x (which controls the decay of transition rates, see [4]) for potentiation and depression in the wild-type as well as potentiation in the $D^bK^{b-/-}$ mice. We will use a larger value for x for depression in the $D^bK^{b-/-}$ mice.

The values used for all these parameters in simulations are listed in Table 1.

1.1.1 Pooled resource model

Suppose that there is some resource required for potentiation/depression that is shared between P synapses and is depleted as more synapses are potentiated/depressed and replenished when this is reversed. We can avoid going beyond the independent synapse model by modelling this pool of synapse as a single compound synapse.

We will model the individual synapses with the two-state model. Let $i = 0 \dots P$ be the number of them that are potentiated. We will model the effect of resource depletion linearly with the potentiation/depression probabilities for the individual synapses:

$$\begin{aligned} q^{\text{pot}} &= \frac{(P-i-1)q_{\text{max}} + i q_{\text{min}}}{P-1}, & i = 0 \dots P-1, \\ q^{\text{dep}} &= \frac{(i-1)q_{\text{max}} + (P-i)q_{\text{min}}}{P-1}, & i = 1 \dots P. \end{aligned} \tag{4}$$

At each plasticity event for the compound synapse, one of the individual synapses will be chosen randomly for update. This effectively reduces the transition probabilities by $1/P$.

This compound synapse would seem to have 2^P internal states. However, we need only keep track of the number of potentiated synapses, not their identity, leaving $M = P + 1$ states. The transition network will then have a multistate topology (see Figure 1c) but the transition probabilities will no longer be uniform and the weight of the compound synapse is the mean of its constituent synapses:

$$\mathbf{w}_i = \frac{2i}{P} - 1. \tag{5}$$

Figure 1: Transition probabilities for different models. Potentiation induces transitions indicated by orange arrows, depression indicated by blue arrows. States of strong/weak synaptic weight indicated by orange/blue circles. (a) In the serial model the transition probabilities for potentiation/depression are all equal and it is parameterised by these two values. The synaptic weight takes only two values, ± 1 . (b) The two-state model is parameterised by the two transition probabilities. (c) In the multistate model the transition probabilities for potentiation/depression are all equal and it is parameterised by these two values. The synaptic weight varies linearly in the interval $[-1, 1]$. (d) In the cascade model, the transition probabilities decay geometrically with a parameter x (see [4]) and synaptic weight takes only two values.

Figure 2: The pooled resource model. Several two-state synapses share resources that are required for potentiation and depression. These resources are depleted as more synapses are potentiated or depressed. This pool of synapses can be modelled as one compound synapse.

The Markov process is lumpable wrt. this partition of states (see [5, §6.3] for the discrete time version and [6, 7] for continuous time). The transition probabilities between lumps i and j is computed by choosing one state from lump i and summing the transition probabilities to all states in lump j . The result must be the same for all states in lump i .

For any state in lump i , there are $P - i$ synapses that can be potentiated to go to lump $i + 1$. Each of these transition probabilities is q^{pot}/P . Similarly, there are i synapses that can be depressed to go to lump $i - 1$. Each of these transition probabilities is q^{dep}/P . Thus:

$$\begin{aligned} \mathbf{M}_{ii+1}^{\text{pot}} &= \left[\frac{(P - i - 1)q_{\text{max}} + i q_{\text{min}}}{P - 1} \right] \frac{P - i}{P}, & i = 0 \dots P - 1, \\ \mathbf{M}_{ii-1}^{\text{dep}} &= \left[\frac{(i - 1)q_{\text{max}} + (P - i)q_{\text{min}}}{P - 1} \right] \frac{i}{P}, & i = 1 \dots P, \end{aligned} \tag{6}$$

with all other off-diagonal elements equal to zero. The diagonal elements are chosen so that the rows sum to one.

This model is parameterised by the range of values, $q \in [q_{\text{min}}, q_{\text{max}}]$, for potentiation and depression. We will use the same values for potentiation and depression in the wild-type as well as potentiation in the $\text{D}^{\text{b}}\text{K}^{\text{b-/-}}$ mice. We will use larger values for depression in the $\text{D}^{\text{b}}\text{K}^{\text{b-/-}}$ mice. In the main text, we consider a version of this model that has resource depletion for depression only, so that potentiation transition probabilities are unaffected by the number of potentiated synapses. This is done by setting $q_{\text{max}}^{\text{pot}} = q_{\text{min}}^{\text{pot}}$. The values of these parameters are listed in Table 1.

1.1.2 Non-uniform multistate model

This model is similar to the multistate model (see Figure 1c), as it only has transitions between adjacent states and a linearly varying synaptic weight. However, like the cascade model (see [4] and Figure 1d), the transition probabilities decay exponentially away from

Non-uniform multistate model

Figure 3: The non-uniform multistate model. Similar to the multistate model, [Figure 1c](#)), the synaptic weight varies linearly in the interval $[-1, 1]$, but the transition probabilities between adjacent states decays exponentially away from the central transition for both potentiation and depression.

the central transition. More precisely:

$$\mathbf{M}_{ii+1}^{\text{pot}} = \mathbf{M}_{i+1i}^{\text{dep}} = x^{\left|\frac{M+1}{2}-i\right|+\frac{1}{2}}, \quad i = 1 \dots M-1, \quad (7)$$

with all other off-diagonal elements equal to zero. The diagonal elements are chosen so that the rows sum to one.

This model is parameterised by the values of x chosen for potentiation and depression. We will use a larger value for depression in the $\text{D}^{\text{b}}\text{K}^{\text{b-/-}}$ mice. The values used are listed in [Table 1](#).

1.2 Model of VOR learning experiment

Training the animal will not change the internal dynamics of a synapse under potentiation or depression. It will change the environment, which will lead to a change in how often potentiation and depression occur. It could be manifested in a change in which synapses are potentiated/depressed, but this could not be captured in this type of model. We will model this by changing $f^{\text{pot/dep}}$, leaving $\mathbf{M}^{\text{pot/dep}}$ unchanged. This approach was used to model motor learning in [\[8\]](#).

The untrained case will be described by $f^{\text{dep}} = f_0^{\text{dep}}$. Gain-increase training will be described by $f^{\text{dep}} = f_{\text{inc}}^{\text{dep}} > f_0^{\text{dep}}$, and gain-decrease training will be described by $f^{\text{dep}} = f_{\text{dec}}^{\text{dep}} < f_0^{\text{dep}}$. Note that the forgetting matrix [\(2\)](#) and the equilibrium distribution [\(3\)](#) depend on f^{dep} , which we will indicate with subscripts.

Before training, the synaptic distribution will be in the equilibrium distribution corresponding to f_0^{dep} . During gain-increase training, it will evolve according to [\(2\)](#) with $f_{\text{inc}}^{\text{pot}}$.

$$\mathbf{p}(t) = \mathbf{p}_0^\infty \exp(rt\mathbf{W}_{\text{inc}}^{\text{F}}). \quad (8)$$

On the other hand, if the gain-increase training follows gain-decrease pre-training for some time period, t_{pre} :

$$\mathbf{p}(t) = \mathbf{p}_0^\infty \exp(rt_{\text{pre}}\mathbf{W}_{\text{dec}}^{\text{F}}) \exp(r(t-t_{\text{pre}})\mathbf{W}_{\text{inc}}^{\text{F}}). \quad (9)$$

We will describe the effect of training by the decrease in mean synaptic weight:

$$L(t) = (\mathbf{p}(0) - \mathbf{p}(t)) \mathbf{w}. \quad (10)$$

If we imagine something like an LN model for the Purkinje cell, the output would depend on some linear combination of the synaptic weights (weighted by the activities of the corresponding parallel fibres). If we're not keeping track of synaptic identity, the most natural linear combination to use would be an equal sum of them all. The behavioural output (VOR gain) will be some unknown, non-linear function of the synaptic weights, so the best we can hope for is to reproduce qualitative features of the experiment, such as whether learning is enhanced or impaired by the mutation or pre-training.

We will assume $f_{\text{WT}}^{\text{dep}} = f_{\text{MHC}}^{\text{dep}}$. This is because the effects of the mutation are well localised to the Purkinje cells, so the activity of the parallel and climbing fibres should not change very much. Therefore the rates of potentiation and depression should not change very much either. This implies that the mean synaptic weight in equilibrium differs between the $\text{D}^b\text{K}^{b-/-}$ mice and wild type, but that is also suggested by the data regarding basal levels of phospho-GluR2 at serine 880. As the mutation produces no change in baseline performance, there must be a compensatory mechanism somewhere else. We will model this compensation as a simple linear offset, as could be produced by another population of neurons/synapses whose effect cancels with these neurons/synapses.

For the most part, we set $f_0^{\text{dep}} = \frac{1}{2}$, $f_{\text{inc}}^{\text{dep}} = f_0^{\text{dep}} + \Delta f$ and $f_{\text{dec}}^{\text{dep}} = f_0^{\text{dep}} - \Delta f$, with $\Delta f > 0$. We use the same values for wild-type and $\text{D}^b\text{K}^{b-/-}$ mice for the reasons discussed above. We will mostly treat gain-increase and decrease symmetrically, but this is not necessary. We could adjust r to keep r^{pot} unchanged, if so desired, but this would only change the overall timescale and would not affect any of the qualitative comparisons that we are concerned with here. The values of these parameters are listed in [Table 1](#).

We are also assuming that the relation between VOR gain and mean synaptic weight is the same for $\text{D}^b\text{K}^{b-/-}$ mice and wild-type, except for a linear offset to compensate for the difference in equilibrium weights mentioned above. This ensures that the qualitative questions mentioned above (enhancement or impairment of learning) will not be affected.

2 Simulation and analysis of models

The features of the actual experiments that we'd like to capture are:

1. Without pre-training, gain-increase learning is significantly faster in the wild-type than in the $\text{D}^b\text{K}^{b-/-}$ mice.
2. For the wild-type, gain-increase learning is significantly faster without pre-training than with it.
3. For the $\text{D}^b\text{K}^{b-/-}$ mice, gain-increase learning is significantly faster with pre-training than without it.

Model	# states	pot	WT dep	D ^b K ^{b-/-} dep	Δf	rt_{pre}
Serial	10	$q = 0.3$	$q = 0.3$	$q = 0.4$	0.1	20
Serial	10	$q = 0.3$	$q = 0.3$	$q = 0.4$	0.3	20
Serial	10	$q = 0.3$	$q = 0.3$	$q = 0.4$	0.45	30
Two-state	2	$q = 0.1$	$q = 0.1$	$q = 0.2$	0.1	5
Multistate	10	$q = 0.3$	$q = 0.3$	$q = 0.4$	0.3	5
Pooled res.	7	$q = 0.008$	$q \in [0.0006, 0.6]$	$q \in [0.001, 1]$	0.4	20
Cascade	10	$x = 0.25$	$x = 0.25$	$x = 0.33$	0.3	20
Cascade	10	$x = 0.25$	$x = 0.25$	$x = 0.33$	0.3	100
Non-uni. MS	10	$x = 0.25$	$x = 0.25$	$x = 0.33$	0.3	150

Table 1: Parameters used in simulations.

4. After pre-training, gain-increase learning is significantly faster in the D^bK^{b-/-} mice than in the wild-type.
5. Gain-decrease pre-training is slightly faster in the wild-type, but not significantly so.

These questions will not be affected by any output nonlinearity, as long as it is monotonic and fixed. We will not worry too much about [item 5](#), as gain-decrease learning uses a different mechanism to gain-increase. We are only modelling the effect of gain-decrease training on *these* synapses.

We will not worry too much about the curvature of the learning curves, as this can be changed by the nonlinear relation between synaptic weight and VOR gain. However, both the wild-type and D^bK^{b-/-} mice should be affected in the same way, so the difference in the curvature of the D^bK^{b-/-} mice and wild-type curves after pre-training would be nice to capture.

We will try to gain some analytic insight to some of these models by looking at the slope of the learning curve at the start of gain-increase training. This is proportional to the net-flux from the states with strong synaptic weight to the weaker states, measured using the transition probabilities for gain-increase but the equilibrium distribution for either untrained or gain-decrease, assuming that pre-training lasts long enough to reach the equilibrium distribution for gain-decrease. This should be multiplied by the difference in synaptic weights. But, as this quantity is constant within a model and doesn't change when comparing wild-type and D^bK^{b-/-} mice or with/without pre-training, it can be ignored.

The values for all parameters we will use can be found in [Table 1](#).

2.1 Serial model

The results of simulations of the serial model can be seen in [Figure 4](#), [Figure 5](#) and [Figure 6](#). However, we can get some insight into this model analytically.

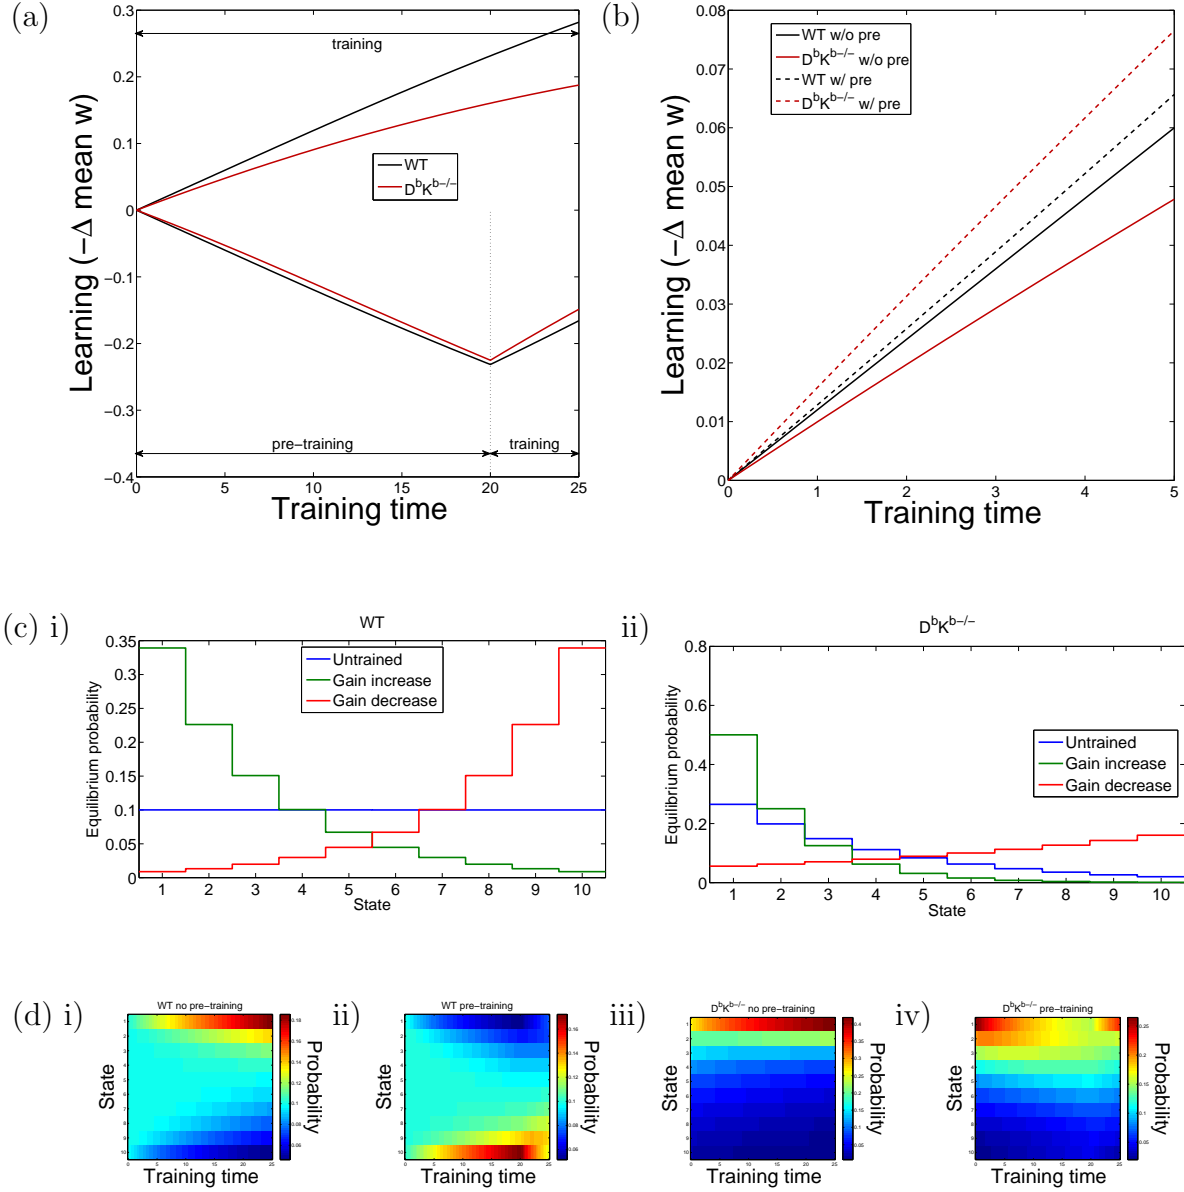

Figure 4: Simulation results for the **serial** model with weak training ($\Delta f = 0.1$). Other parameters can be found in row 1 of Table 1. Time is measured in units of $1/r$, the mean time between plasticity events. (a) Learning curves for wild-type and $D^bK^{b-/-}$ mice with and without pre-training. (b) Learning curves restricted to gain-increase training. (c) Equilibrium distributions without training or with gain-increase/decrease training for (i) wild-type and (ii) $D^bK^{b-/-}$ mice, with states of weak synaptic strength to the left and strong states to the right. (d) Evolution of probability distributions for (i,ii) wild-type and (iii,iv) $D^bK^{b-/-}$ mice without (i,iii) and with (ii,iv) pre-training, with states of weak synaptic strength at the top and strong states underneath.

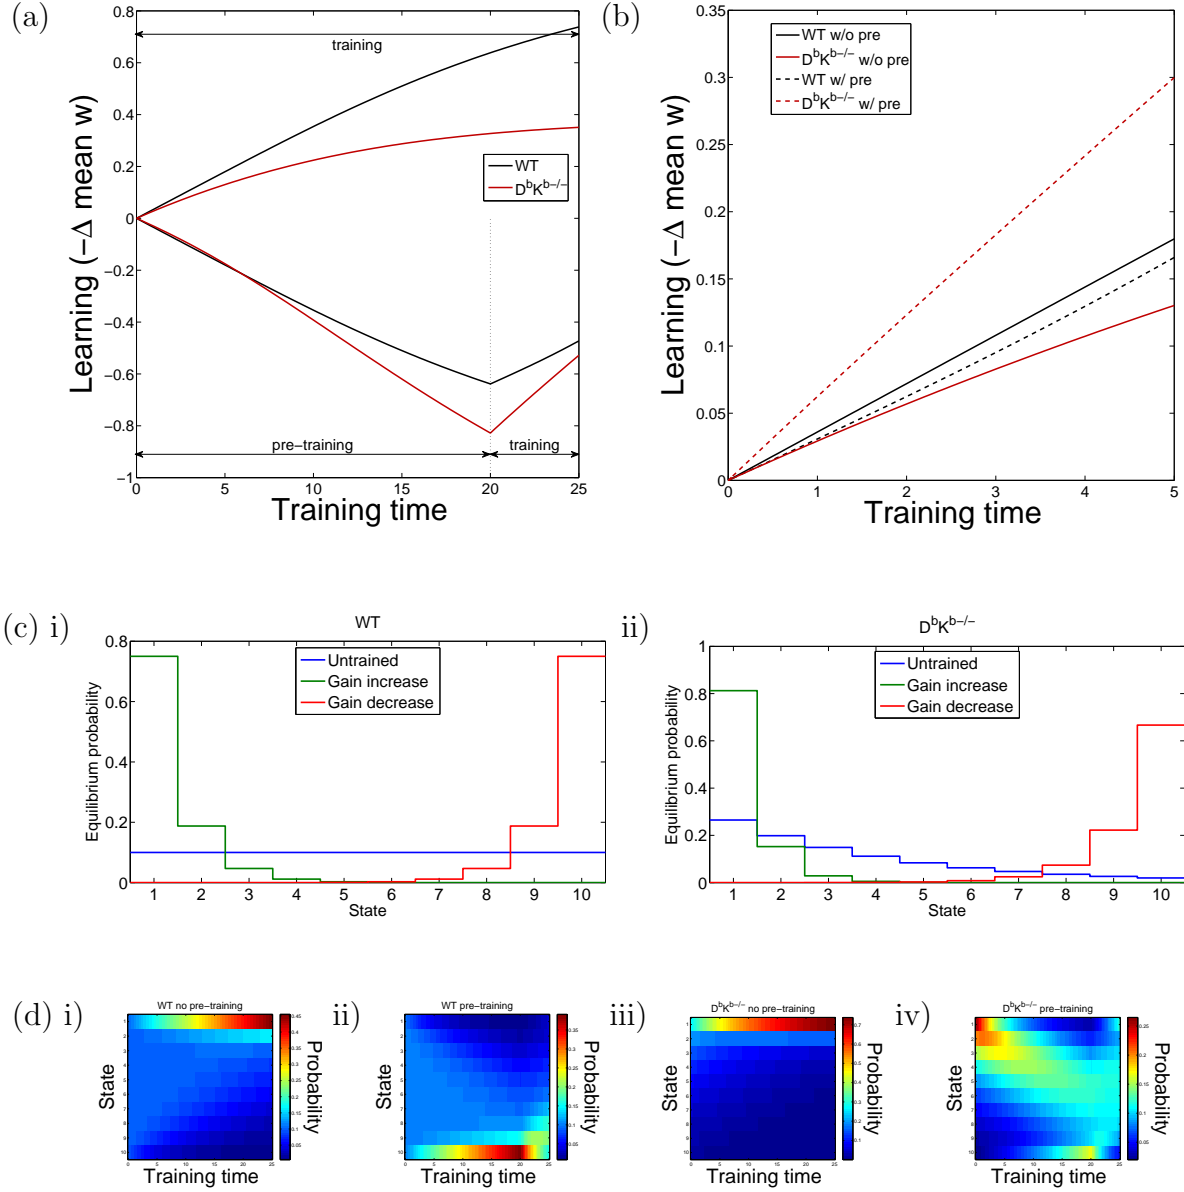

Figure 5: Simulation results for the **serial** model with moderate training ($\Delta f = 0.3$). Other parameters can be found in row 2 of Table 1. Time is measured in units of $1/r$, the mean time between plasticity events. (a) Learning curves for wild-type and $D^bK^{b-/-}$ mice with and without pre-training. (b) Learning curves restricted to gain-increase training. (c) Equilibrium distributions without training or with gain-increase/decrease training for (i) wild-type and (ii) $D^bK^{b-/-}$ mice, with states of weak synaptic strength to the left and strong states to the right. (d) Evolution of probability distributions for (i,ii) wild-type and (iii,iv) $D^bK^{b-/-}$ mice without (i,iii) and with (ii,iv) pre-training, with states of weak synaptic strength at the top and strong states underneath.

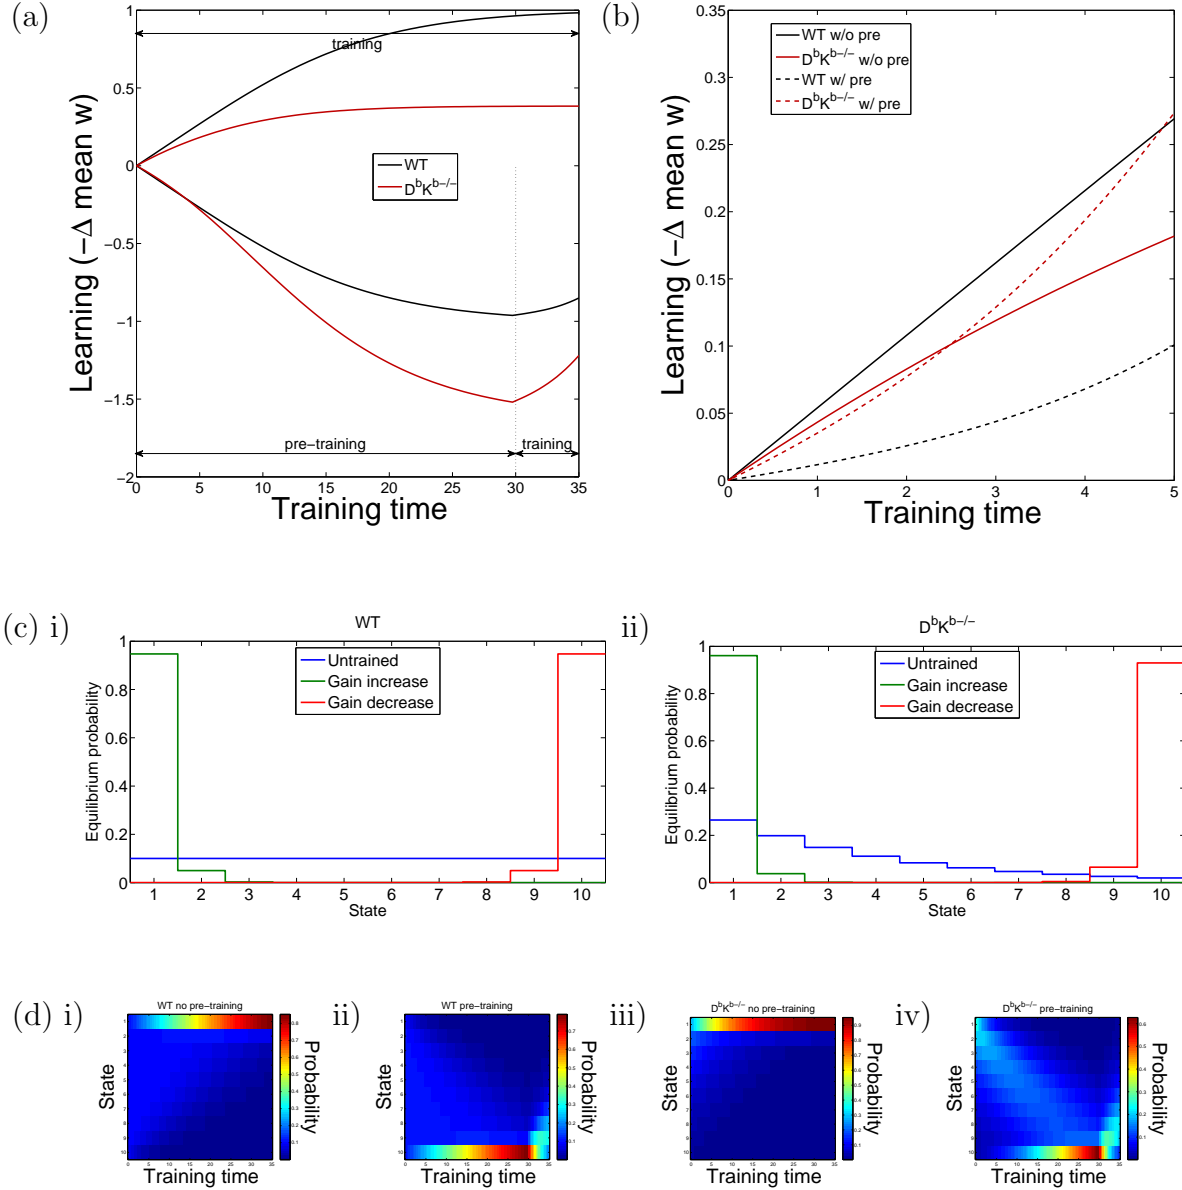

Figure 6: Simulation results for the **serial** model with strong training ($\Delta f = 0.45$). Other parameters can be found in row 3 of Table 1. Time is measured in units of $1/r$, the mean time between plasticity events. (a) Learning curves for wild-type and $D^bK^{b-/-}$ mice with and without pre-training. (b) Learning curves restricted to gain-increase training. (c) Equilibrium distributions without training or with gain-increase/decrease training for (i) wild-type and (ii) $D^bK^{b-/-}$ mice, with states of weak synaptic strength to the left and strong states to the right. (d) Evolution of probability distributions for (i,ii) wild-type and (iii,iv) $D^bK^{b-/-}$ mice without (i,iii) and with (ii,iv) pre-training, with states of weak synaptic strength at the top and strong states underneath.

Consider the general uniform multistate model. Then the equilibrium distribution is given by

$$\mathbf{p}_i^\infty = \frac{1 - \alpha}{1 - \alpha^M} \alpha^{i-1}, \quad \text{where} \quad \alpha = \frac{f^{\text{pot}} q^{\text{pot}}}{f^{\text{dep}} q^{\text{dep}}}. \quad (11)$$

If we take the limit $\alpha \rightarrow 1$, this becomes $\frac{1}{M}$.

The net-flux from the $\mathbf{w} = +1$ states to the $\mathbf{w} = -1$ states is:

$$\Phi = \mathbf{p}_{M/2+1}^\infty f'^{\text{dep}} q^{\text{dep}} - \mathbf{p}_{M/2}^\infty f'^{\text{pot}} q^{\text{pot}} = \frac{1 - \alpha}{1 - \alpha^M} \alpha^{M/2-1} (\alpha - \alpha') f'^{\text{dep}} q^{\text{dep}}, \quad (12)$$

where primed values correspond to the new value of f^{pot} .

First, consider the wild-type, for which $q^{\text{pot}} = q^{\text{dep}} = q$. Without pre-training:

$$\Phi = \frac{2\Delta f q}{M}. \quad (13)$$

With pre-training:

$$\begin{aligned} \Phi &= 16(\Delta f)^2 q \frac{(1 + 2\Delta f)^{M/2-1} (1 - 2\Delta f)^{M/2-1}}{(1 + 2\Delta f)^M - (1 - 2\Delta f)^M} \\ &= \frac{4\Delta f q}{M} + \mathcal{O}(\Delta f)^2. \end{aligned} \quad (14)$$

So, we see that pre-training will speed up learning when Δf is small (in absolute value), as seen in [Figure 4b](#) (black curves). On the other hand, if Δf is close to $\frac{1}{2}$, pre-training will initially slow down learning a lot due to the factor of $(1 - 2\Delta f)^{M/2-1}$, as seen in [Figure 6b](#).

Intuitively, the flux depends on the slope of the distribution at the centre of the chain (with an offset due to the difference between f^{pot} and f^{dep}). Pre-training has two effects: it produces a slope in the right direction (see [Figure 4c](#), red trace), but it also reduces the distribution at the centre (see [Figure 6c](#), red trace). For small Δf , the first effect is stronger and learning speeds up. For larger Δf , the second effect wins and learning slows down.

This impaired learning after pre-training in the wild-type is caused by the excessive potentiation pushing the synapses away from the central transition that generates the learning signal. Essentially, this model has a form of metaplasticity where repeated potentiation makes subsequent depression harder. This allows excessive pre-training to impair learning, despite increasing the number of potentiated synapses.

Now, consider the $\text{D}^{\text{b}}\text{K}^{\text{b-/-}}$ mice, for which we define $\beta = q^{\text{pot}}/q^{\text{dep}} < 1$, and we set $q^{\text{pot}} = q$. Without pre-training:

$$\Phi = 2\Delta f q \frac{(1 - \beta)\beta^{M/2-1}}{1 - \beta^M}. \quad (15)$$

This will be smaller than (13) if $\beta < \beta^*(M)$, where $\beta^*(M)$ is defined as the value at which they are equal. This function is plotted in [Figure 7a](#), where we can see that it approaches 1 rapidly as we increase M .

There are two effects here as well. Smaller β will increase the probability of crossing the centre of the chain, speeding up learning, but it will also concentrate probability at the ends of the chain, depleting the centre and slowing down learning (see [Figure 6cii](#), blue trace). The first effect goes like $1/\beta$, whereas the second goes like $\beta^{M/2}$ and will be more significant for smaller β or in a longer chain. This exponential decay in the initial distribution is what allows the saturation bias to overwhelm the increases intrinsic plasticity rate and lead to impaired learning with enhanced plasticity. It is important that a learning signal is only generated by the central transition so that the exponential decay can take effect.

With pre-training:

$$\begin{aligned}\Phi &= 4\Delta f q \frac{(1 - 2\Delta f) - \beta(1 + 2\Delta f)}{(1 - 2\Delta f)^M - \beta^M(1 + 2\Delta f)^M} [\beta(1 - 2\Delta f)(1 + 2\Delta f)]^{M/2-1} \\ &= 4\Delta f q \frac{(1 - \beta)\beta^{M/2-1}}{1 - \beta^M} + \mathcal{O}(\Delta f)^2.\end{aligned}\tag{16}$$

Once again, we see that pre-training will speed up learning when Δf is small, whereas, if Δf is close to $-\frac{1}{2}$, pre-training will initially slow down learning.

Let us define $\Delta f^*(\beta, M)$ to be the value at which (15) and (16) are equal. Values of Δf that are larger than this (stronger training) will correspond to slower learning after pre-training. As we would like pre-training to slow down learning in the wild-type but speed it up in the $D^bK^{b-/-}$ mice, it would seem that we require $\Delta f^*(1, M) < \Delta f < \Delta f^*(\beta, M)$ (remembering that the wild-type corresponds to $\beta = 1$). As we see in [Figure 7b](#), $\Delta f^*(\beta, M) > \Delta f^*(1, M)$, so this range always exists. We can see an example of this in [Figure 5b](#).

However, this is only the initial, instantaneous rate of change. Let's look at [Figure 6b](#), for which $\Delta f > \Delta f^*(\beta, M)$, so that pre-training initially slows down learning for both wild-type and $D^bK^{b-/-}$ mice. We see that the pre-trained curve can rapidly catch up with the un-pre-trained one, due to the mass of probability concentrated at the end of the chain (see [Figure 6c](#), red trace) drifting to the centre. This happens sooner for the $D^bK^{b-/-}$ mice than the wild-type, due to the stronger depressing transitions. This means that there is an intermediate range of time-scales over which pre-training does slow down learning in the wild-type but speed it up in the $D^bK^{b-/-}$ mice, even outside the desired range of values for Δf . As we see in [Figure 5b](#) (black curves), even when we are in this range, the period of time for which pre-training impairs learning in the wild-type can be very small.

In conclusion, if we choose $\beta < \beta^*(M)$, $\Delta f > \Delta f^*(1, M)$ and look at intermediate time-scales, we will see that the $D^bK^{b-/-}$ mice learn slower than wild-type without pre-training, and that pre-training speeds up learning in the $D^bK^{b-/-}$ mice but slows it down in the wild-type. However, in this case pre-training proceeds much faster in the $D^bK^{b-/-}$ mice than wild-type (see [Figure 5a](#) and [Figure 6a](#), lower curves), which is *not* seen in the experiment.

Now consider what would happen if we did not treat gain-increase and gain-decrease

Figure 7: The functions (a) $\beta^*(M)$, which describes when the $D^bK^{b-/-}$ mice have impaired learning, and (b) $\Delta f^*(\beta, M)$ for $M = 10$, which describes when pre-training enhances learning.

symmetrically. Let us set $f_{dec}^{pot} = f_0^{pot} - \overline{\Delta f}$. Then, (16) becomes

$$\begin{aligned} \Phi &= 2 (\Delta f + \overline{\Delta f}) q \frac{(1 - 2\overline{\Delta f}) - \beta(1 + 2\overline{\Delta f})}{(1 - 2\overline{\Delta f})^M - \beta^M(1 + 2\overline{\Delta f})^M} [\beta(1 - 2\overline{\Delta f})(1 + 2\overline{\Delta f})]^{M/2-1} \\ &= 2 (\Delta f + \overline{\Delta f}) q \frac{(1 - \beta)\beta^{M/2-1}}{1 - \beta^M} + \mathcal{O}(\Delta f, \overline{\Delta f})^2. \end{aligned} \quad (17)$$

We can then look at the wild-type by setting $\beta = 1$:

$$\begin{aligned} \Phi &= 8 \overline{\Delta f} (\Delta f + \overline{\Delta f}) q \frac{(1 - 2\overline{\Delta f})^{M/2-1}(1 + 2\overline{\Delta f})^{M/2-1}}{(1 + 2\overline{\Delta f})^M - (1 - 2\overline{\Delta f})^M} \\ &= \frac{2 (\Delta f + \overline{\Delta f}) q}{M} + \mathcal{O}(\Delta f, \overline{\Delta f})^2. \end{aligned} \quad (18)$$

We can see from these formulae that, if we want pre-training to impair learning in wild-type, but enhance it in the $D^bK^{b-/-}$ mice, the important thing is to have *strong pre-training*, not strong training. Thus, removing the symmetry between gain-increase and gain-decrease will not help with the most unrealistic feature of this model – the fact that pre-training proceeds much faster in the $D^bK^{b-/-}$ mice than wild-type.

Finally, we note that, in the case of medium or strong pre-training, we see positive curvature in the learning curve after pre-training for a longer time in wild-type than in the $D^bK^{b-/-}$ mice (see Figure 5b and Figure 6b, dashed curves). This is due to the mass of probability at the right end of the chain (see Figure 5c and Figure 6c, red trace) that is unable to contribute to change in synaptic weight until it has drifted to the centre. This will last for a shorter time in the $D^bK^{b-/-}$ mice, due to the enhanced transitions. This will not be a feature of any of the other models that we study here. Now, the curvature can be changed by the nonlinear relation between synaptic weight and VOR gain, but both curves would be affected in the same way. The difference in these two curvatures is therefore a good feature of this model.

2.2 Two-state model

The results of simulations of the two-state model can be seen in [Figure 8](#). However, this model can be solved exactly:

$$\mathbf{p}^\infty = \frac{(f^{\text{dep}} q^{\text{dep}}, f^{\text{pot}} q^{\text{pot}})}{\lambda}, \quad \mathbf{p}(t) = \mathbf{p}^\infty + (\mathbf{p}(t) - \mathbf{p}^\infty) e^{-\lambda t},$$

where $\lambda = f^{\text{pot}} q^{\text{pot}} + f^{\text{dep}} q^{\text{dep}}$. (19)

But it is easier to just substitute $M = 2$ into the formulae in [§2.1](#). In this case, the initial rate of change and the total change encapsulate the whole solution, as there is only a single exponential decay.

First, consider the wild-type, for which $q^{\text{pot}} = q^{\text{dep}} = q$. Without pre-training:

$$\Phi = \Delta f q. \quad (20)$$

With pre-training:

$$\Phi = 2\Delta f q. \quad (21)$$

So, we see that pre-training will always speed up learning, unlike what is seen in the experiment. This can be seen in [Figure 8b](#) (black curves).

Now, consider the $\text{D}^{\text{b}}\text{K}^{\text{b-/-}}$ mice, for which we define $\beta = q^{\text{pot}}/q^{\text{dep}} < 1$, and we set $q^{\text{pot}} = q$. Without pre-training:

$$\Phi = \frac{2\Delta f q}{1 + \beta}, \quad (22)$$

which is always larger than (20), unlike what is seen in the experiment. This is also seen in [Figure 8a,b](#) (solid curves). As discussed above (below (15)), the larger value of $q^{\text{dep}} = q/\beta$ has two effects. Smaller β will increase the probability of depression, speeding up learning, but it will also decrease the probability of being ready for depression, slowing down learning. For the serial model, we argued that the first effect goes like $1/\beta$, whereas the second goes like $\beta^{M/2}$ to leading order. Here $M = 2$, so the leading part of the two effects will cancel. The subleading effects (the normalisation of the probabilities) are responsible for the faster learning in the $\text{D}^{\text{b}}\text{K}^{\text{b-/-}}$ mice.

With pre-training:

$$\Phi = 4\Delta f q \frac{(1 - 2\Delta f) - \beta(1 + 2\Delta f)}{(1 - 2\Delta f)^2 - \beta^2(1 + 2\Delta f)^2}. \quad (23)$$

As we've already ruled out this model, we won't waste any time analysing this formula.

We made a number of assumptions in our analysis so far. Before we declare this model to be falsified, we should think about what would happen if we relaxed these assumptions and explored a larger parameter space.

First, we assumed that the wild type had symmetric potentiation and depression. Relaxing this assumption would correspond modelling the wild-type like the $\text{D}^{\text{b}}\text{K}^{\text{b-/-}}$ mice,

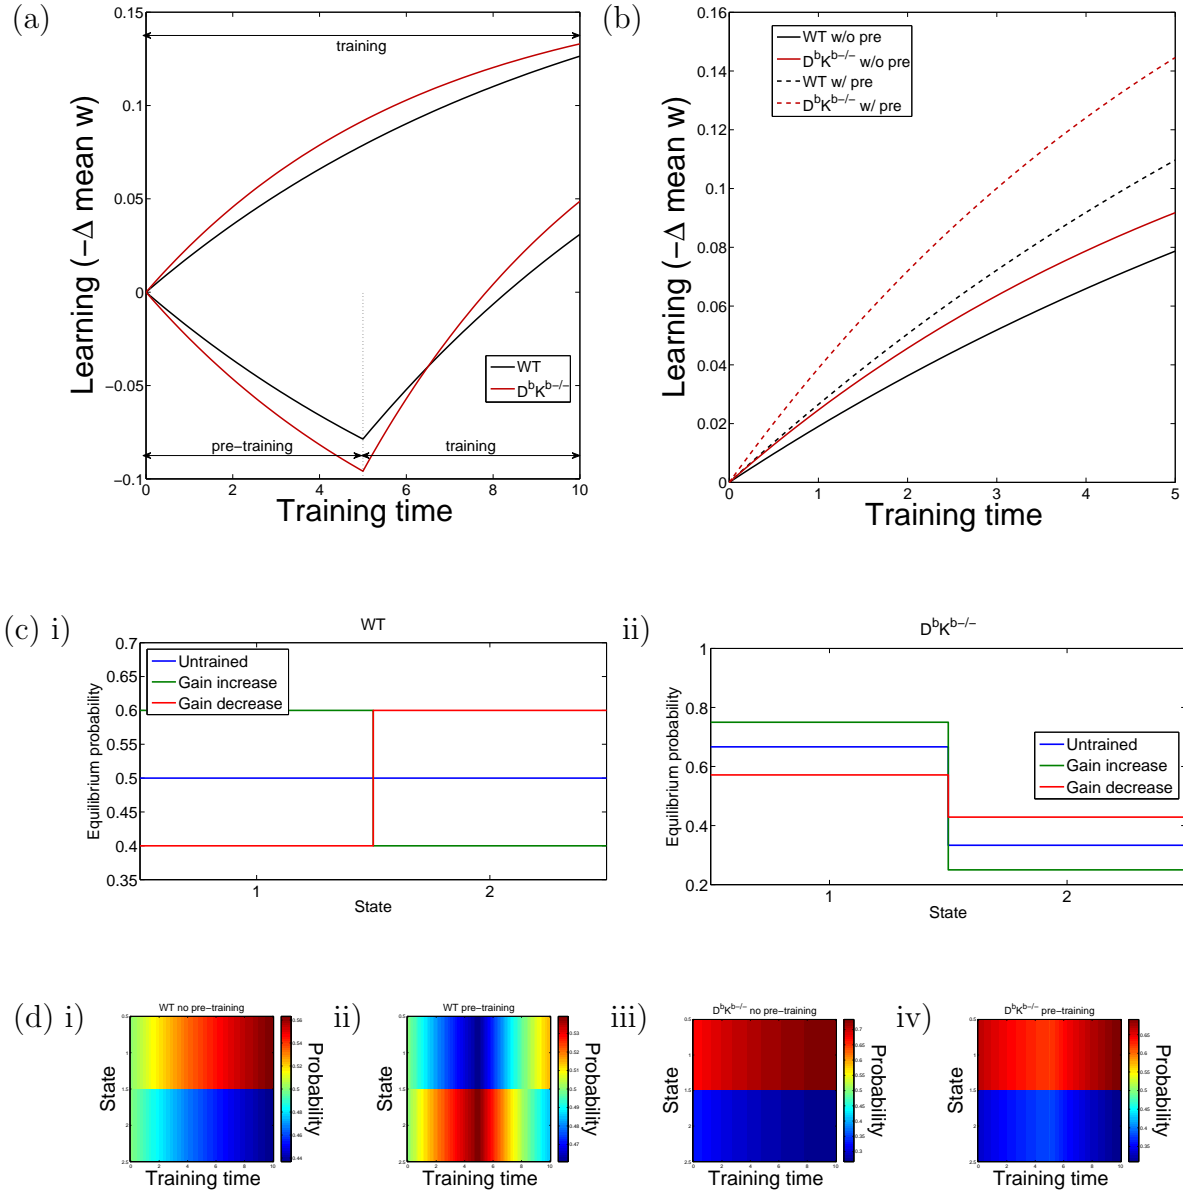

Figure 8: Simulation results for the **two-state model** model. Parameters can be found in row 4 of Table 1. Time is measured in units of $1/r$, the mean time between plasticity events. (a) Learning curves for wild-type and $D^bK^{b-/-}$ mice with and without pre-training. (b) Learning curves restricted to gain-increase training. (c) Equilibrium distributions without training or with gain-increase/decrease training for (i) wild-type and (ii) $D^bK^{b-/-}$ mice, with states of weak synaptic strength to the left and strong states to the right. (d) Evolution of probability distributions for (i,ii) wild-type and (iii,iv) $D^bK^{b-/-}$ mice without (i,iii) and with (ii,iv) pre-training, with states of weak synaptic strength at the top and strong states underneath.

but with a different value for β . We will still have $\beta_{\text{MHC}} < \beta_{\text{WT}}$, and looking at (22) tell us that we would still have faster learning in the $\text{D}^{\text{b}}\text{K}^{\text{b-/-}}$ mice.

Secondly, we assumed that there would be equal rates of potentiation and depression in the untrained situation. However, relaxing this assumption merely changes (22) to

$$\Phi = \frac{\Delta f q}{f^{\text{dep}} + \beta f^{\text{pot}}} = \frac{\Delta f q^{\text{pot}} q^{\text{dep}}}{f^{\text{dep}} q^{\text{dep}} + f^{\text{pot}} q^{\text{pot}}}. \quad (24)$$

This will not change our conclusions either.

As we didn't need the pre-training paradigm to rule out this model, we don't need to look at removing the symmetry between gain-increase and decrease.

The only thing we have to worry about is when the wild-type catches up with the $\text{D}^{\text{b}}\text{K}^{\text{b-/-}}$ mice. As the total change will be larger for the wild-type than $\text{D}^{\text{b}}\text{K}^{\text{b-/-}}$ mice, it must overtake eventually. If this happens early enough, the initial period, where the $\text{D}^{\text{b}}\text{K}^{\text{b-/-}}$ mice learns faster than wild-type, would not be seen in the experiment. However, the timescale for this crossover would be similar to the timescale of the exponentials. In the data, it looks like that timescale is longer than the gaps between successive measurements, so we needn't worry about this.

Intuitively, this model is missing two features of the [serial model](#). First, it does not have the exponential amplification of the effect of initial saturation bias because this model does not have a chain of states for the distribution to decay across. Second, it does not have the metaplastic effect where repeated potentiation makes future depression harder, as potentiation will merely increase the number of potentiated synapses.

2.3 Multistate model

In this section, we will consider the multistate model as originally defined in [2], i.e. with linearly varying synaptic weight:

$$\mathbf{w}_i = \frac{2i - M - 1}{M - 1}. \quad (25)$$

The numerical results can be seen in [Figure 9](#), but we can get some analytic insight into this model as well. In essence, this model is like a series of two-state models attached to each other, in contrast to the serial model for which the synaptic weight only changes between one of the pairs of states.

The equilibrium distribution, (11), still applies. However, now the rate of change of our learning metric, (10), will be proportional to the sum of the net fluxes between adjacent states:

$$\begin{aligned} \Phi &= \sum_{i=1}^{M-1} \mathbf{p}_{i+1}^{\infty} f'^{\text{dep}} q^{\text{dep}} - \mathbf{p}_i^{\infty} f'^{\text{pot}} q^{\text{pot}} = \sum_{i=1}^{M-1} \mathbf{p}_i^{\infty} (\alpha - \alpha') f'^{\text{dep}} q^{\text{dep}} \\ &= \frac{1 - \alpha^{M-1}}{1 - \alpha^M} (\alpha - \alpha') f'^{\text{dep}} q^{\text{dep}}. \end{aligned} \quad (26)$$

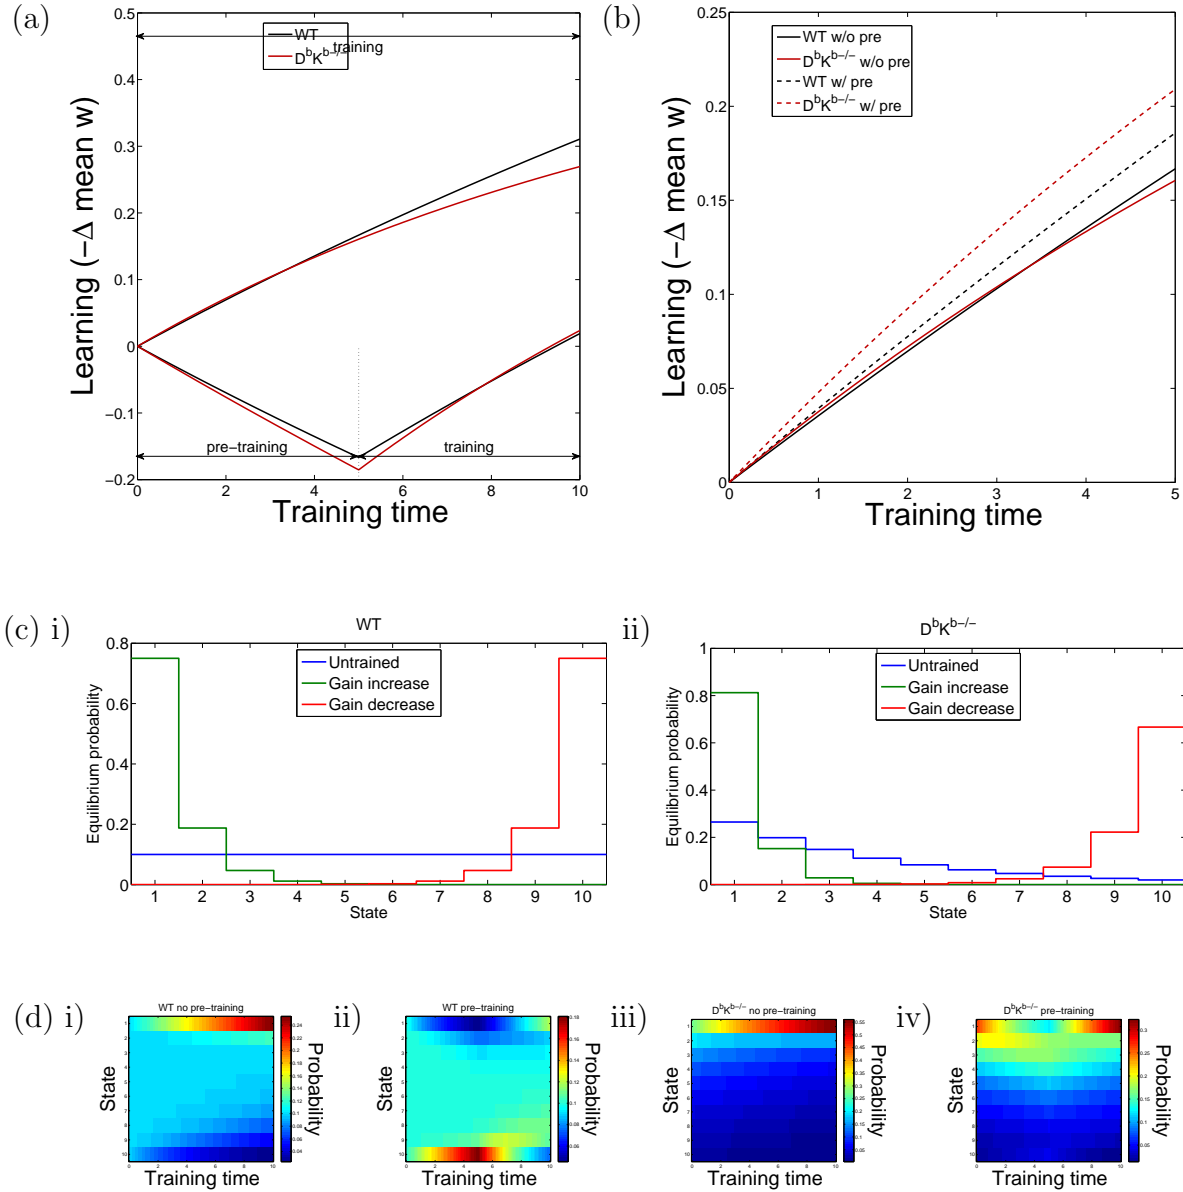

Figure 9: Simulation results for the **multistate model** model. Parameters can be found in row 5 of Table 1. Time is measured in units of $1/r$, the mean time between plasticity events. (a) Learning curves for wild-type and $D^bK^{b-/-}$ mice with and without pre-training. (b) Learning curves restricted to gain-increase training. (c) Equilibrium distributions without training or with gain-increase/decrease training for (i) wild-type and (ii) $D^bK^{b-/-}$ mice, with states of weak synaptic strength to the left and strong states to the right. (d) Evolution of probability distributions for (i,ii) wild-type and (iii,iv) $D^bK^{b-/-}$ mice without (i,iii) and with (ii,iv) pre-training, with states of weak synaptic strength at the top and strong states underneath.

First, consider the wild-type, for which $q^{\text{pot}} = q^{\text{dep}} = q$. Without pre-training:

$$\Phi = 2\Delta f q \frac{M-1}{M}, \quad (27)$$

where, once more, we should note that $\Delta f < 0$. With pre-training:

$$\begin{aligned} \Phi &= 4\Delta f q \frac{(1+2\Delta f)^{M-1} - (1-2\Delta f)^{M-1}}{(1+2\Delta f)^M - (1-2\Delta f)^M} \\ &= 4\Delta f q \frac{M-1}{M} + \mathcal{O}(\Delta f)^2. \end{aligned} \quad (28)$$

Now, consider the $D^bK^{b-/-}$ mice, for which we define $\beta = q^{\text{pot}}/q^{\text{dep}} < 1$, and we set $q^{\text{pot}} = q$. Without pre-training:

$$\Phi = 2\Delta f q \frac{1 - \beta^{M-1}}{1 - \beta^M}. \quad (29)$$

This decreases monotonically in the interval $\beta \in [0, 1]$, therefore this will always be greater than (27). This means that the $D^bK^{b-/-}$ mice will initially learn faster than the wild-type. However, as the wild-type will eventually catch up, and this can happen very quickly, as seen in Figure 9a,b (solid curves).

With pre-training:

$$\begin{aligned} \Phi &= 4\Delta f q \frac{(1-2\Delta f)^{M-1} - \beta^{M-1}(1+2\Delta f)^{M-1}}{(1-2\Delta f)^M - \beta^M(1+2\Delta f)^M} \\ &= 4\Delta f q \frac{1 - \beta^{M-1}}{1 - \beta^M} + \mathcal{O}(\Delta f)^2. \end{aligned} \quad (30)$$

The ratio of this to (29) takes its minimum value at the upper end of the interval $\Delta f \in [0, \frac{1}{2}]$, where it takes the value

$$\frac{\Phi_{\text{w/pre}}}{\Phi_{\text{w/o pre}}} = \frac{1 - \beta^M}{\beta - \beta^M} \longrightarrow \frac{M}{M-1} \quad \text{as } \beta \rightarrow 1, \quad (31)$$

which is always greater than 1. Therefore, pre-training will always enhance learning, for both $D^bK^{b-/-}$ mice and wild-type, as seen in Figure 9b.

Like the [two state model](#), this model is missing two features of the [serial model](#). First, it does not have the amplification of the effect of initial saturation bias as every transition contributes to the learning signal, so the exponentially decaying distribution has no effect. Second, it does not have the metaplastic effect where repeated potentiation makes future depression harder, as potentiation will merely increase the number of potentiated synapses without pushing them away from any boundary between strong and weak states.

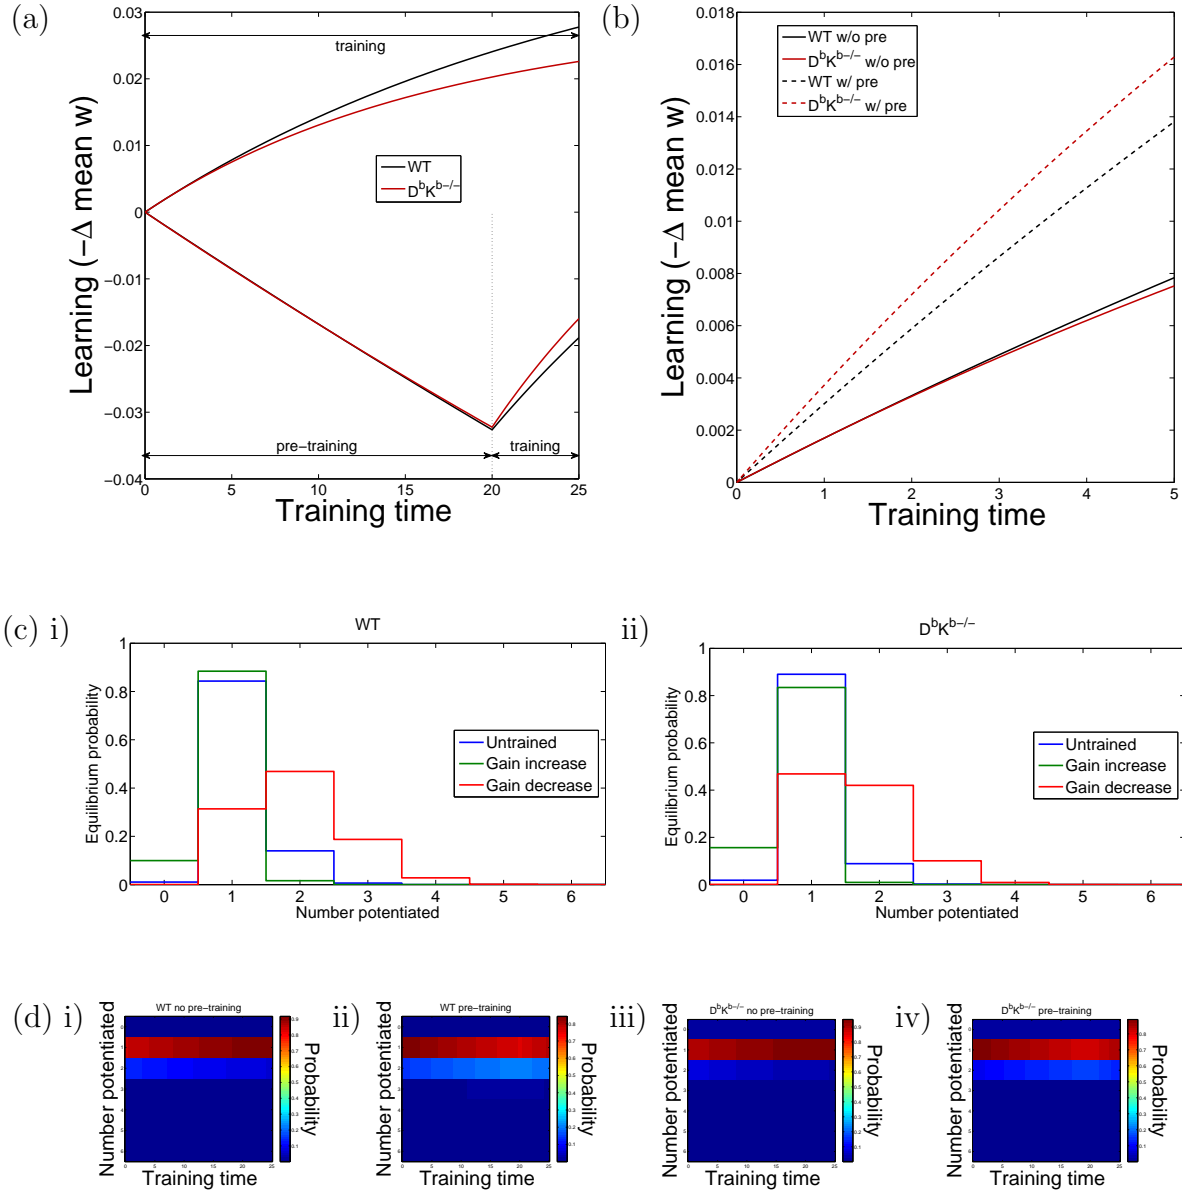

Figure 10: Simulation results for the **pooled resource** model. Parameters can be found in row 6 of Table 1. Time is measured in units of $1/r$, the mean time between plasticity events. (a) Learning curves for wild-type and $D^bK^{b-/-}$ mice with and without pre-training. (b) Learning curves restricted to gain-increase training. (c) Equilibrium distributions without training or with gain-increase/decrease training for (i) wild-type and (ii) $D^bK^{b-/-}$ mice, with states of weak synaptic strength to the left and strong states to the right. (d) Evolution of probability distributions for (i,ii) wild-type and (iii,iv) $D^bK^{b-/-}$ mice without (i,iii) and with (ii,iv) pre-training, with states of weak synaptic strength at the top and strong states underneath.

2.4 Pooled resource model

The results of simulations of the pooled resource model can be seen in [Figure 10](#). It is difficult to study this model analytically. However, the numerical results can help us understand it qualitatively.

If we compare gain-increase learning in the $D^bK^{b-/-}$ mice to wild-type, there are two effects: the increased transition rates speed up learning, but the equilibrium distribution is shifted to the depressed side (compare [Figure 10c](#): [i](#) and [ii](#), blue traces), where there are fewer synapses available for depression and resources are depleted. When resource depletion is sufficiently severe, the second effect dominates and the $D^bK^{b-/-}$ mice learn slower than wild-type (see [Figure 10a,b](#), solid curves), which matches what is seen in the experiment.

Gain-decrease pre-training lessens the second effect, and results in the $D^bK^{b-/-}$ mice learning faster than wild-type (see [Figure 10a,b](#)), as seen in the experiment.

Gain-decrease pre-training will shift the distribution to the potentiated side, where there are more synapses available for depression and resources are more plentiful, for both the $D^bK^{b-/-}$ mice and wild type (see [Figure 10c](#), red traces). This means that the pre-trained animals will learn faster than the untrained one for both $D^bK^{b-/-}$ mice and wild-type (see [Figure 10b](#)). This differs from what is seen experimentally, where the pre-trained wild-type learns slower than the untrained one.

This model shares one feature of the [serial model](#). The effect of initial saturation bias is amplified by resource depletion, allowing for impaired learning with enhanced plasticity. However, it does not have the metaplastic effect where repeated potentiation makes future depression harder, in fact it shows the opposite effect due to resource replenishment, so it can never show impaired learning after pre-training.

2.5 Cascade model

The results of simulations of the cascade model can be seen in [Figure 11](#) and [Figure 12](#). It is difficult to study this model analytically. However, the numerical results can help us understand it qualitatively.

In both of these, we see that the $D^bK^{b-/-}$ mice are slower than wild-type without pre-training but faster with it. This seems to be due to the fact that, without pre-training, very few synapses will be available for depression as most of them are already depressed ([Figure 11cii](#) and [diii](#)). With pre-training, some of them will now be potentiated ([Figure 11cii](#) and [div](#)), and the enhanced depression can speed up learning.

With shorter pre-training, we see that it speeds up learning in both wild-type and $D^bK^{b-/-}$ mice (see [Figure 11b](#)), whereas experimentally this only happens for the $D^bK^{b-/-}$ mice. This is due to the fact that pre-training results in more synapses being potentiated, and thus ready for depression, but does not push them far enough down the cascade for the lower transition probabilities to slow down learning (see [Figure 11dii](#)).

We can see from [Figure 12dii](#) that longer pre-training pushes the synapses further down the cascade, slowing down learning for the wild-type. This effect is weaker for the

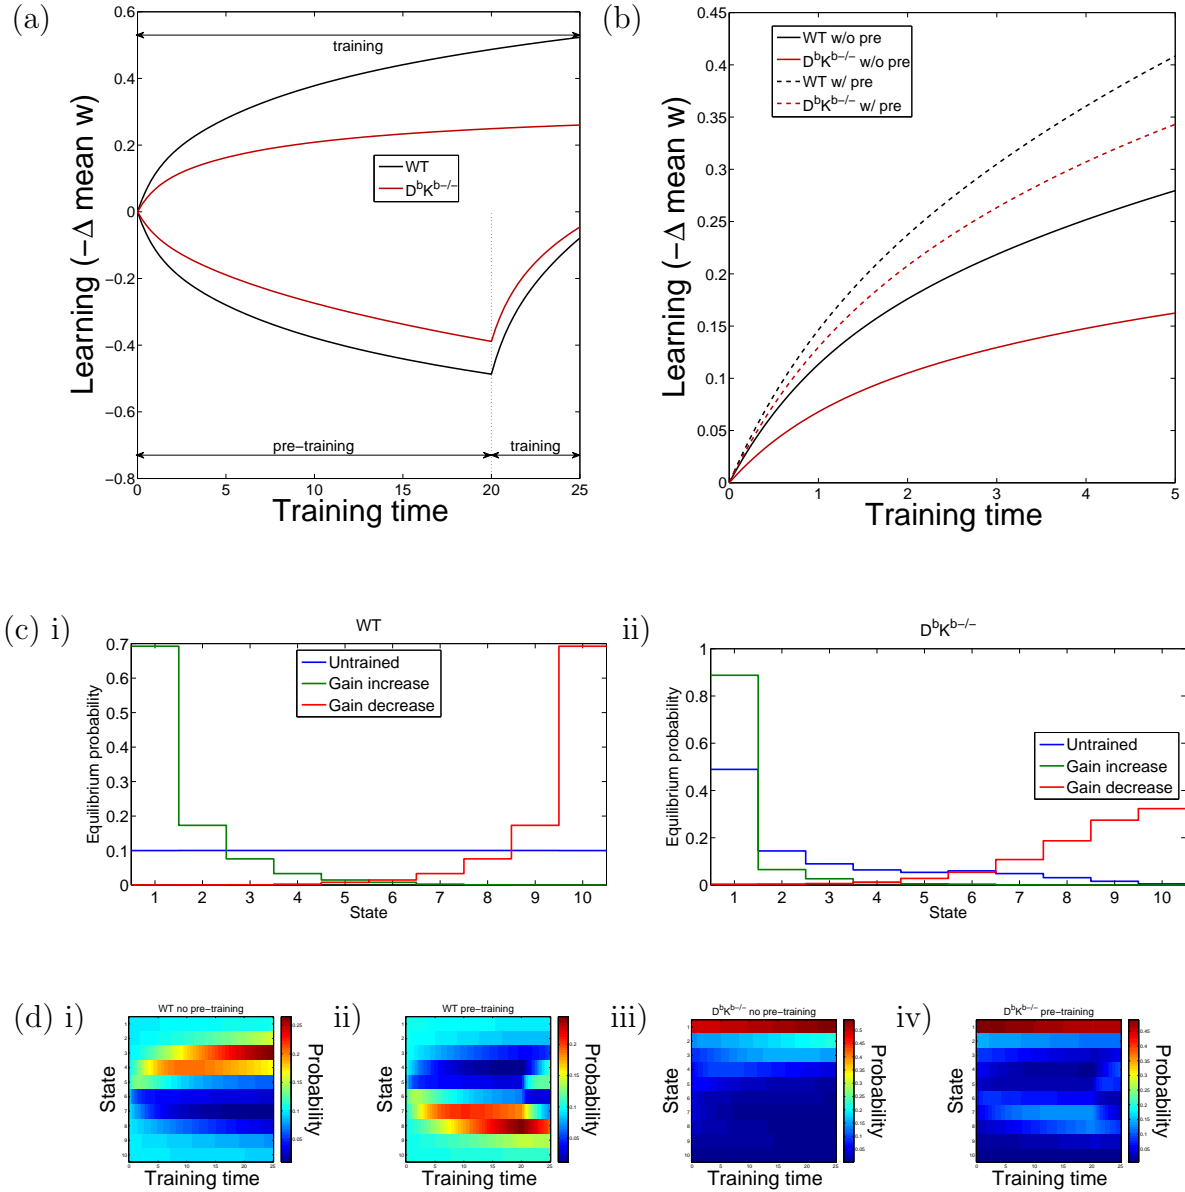

Figure 11: Simulation results for the **cascade** model with short pre-training ($rt_{\text{pre}} = 20$). Other parameters can be found in row 7 of Table 1. Time is measured in units of $1/r$, the mean time between plasticity events. (a) Learning curves for wild-type and $D^bK^{b-/-}$ mice with and without pre-training. (b) Learning curves restricted to gain-increase training. (c) Equilibrium distributions without training or with gain-increase/decrease training for (i) wild-type and (ii) $D^bK^{b-/-}$ mice, with states of weak synaptic strength to the left and strong states to the right. (d) Evolution of probability distributions for (i,ii) wild-type and (iii,iv) $D^bK^{b-/-}$ mice without (i,iii) and with (ii,iv) pre-training, with states of weak synaptic strength at the top and strong states underneath.

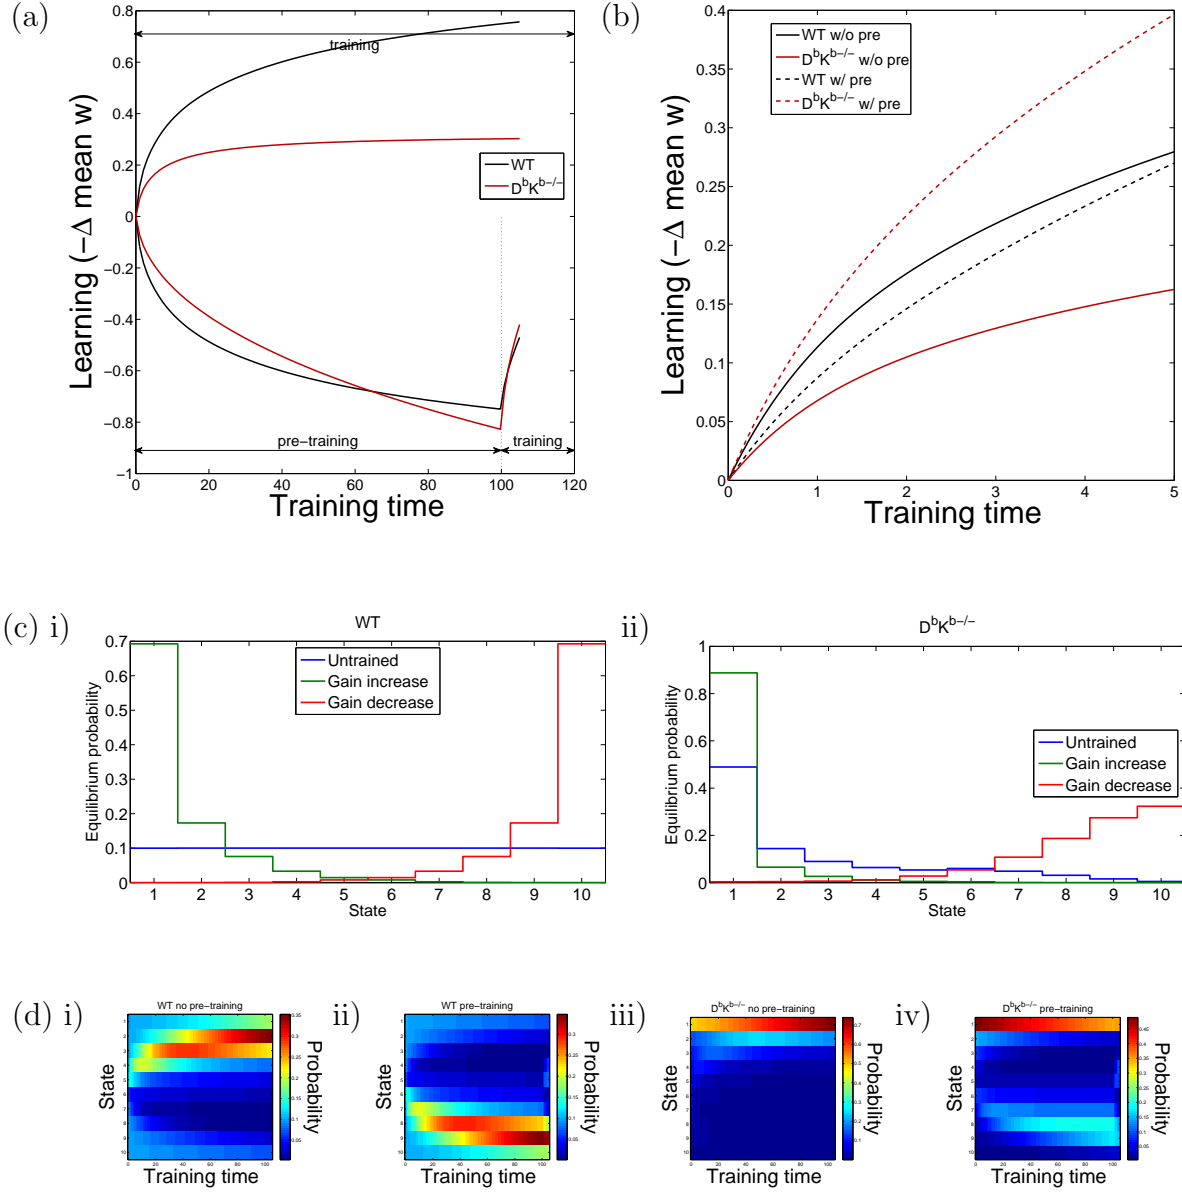

Figure 12: Simulation results for the **cascade** model with long pre-training ($rt_{\text{pre}} = 100$). Other parameters can be found in row 8 of Table 1. Time is measured in units of $1/r$, the mean time between plasticity events. (a) Learning curves for wild-type and $D^bK^{b-/-}$ mice with and without pre-training. (b) Learning curves restricted to gain-increase training. (c) Equilibrium distributions without training or with gain-increase/decrease training for (i) wild-type and (ii) $D^bK^{b-/-}$ mice, with states of weak synaptic strength to the left and strong states to the right. (d) Evolution of probability distributions for (i,ii) wild-type and (iii,iv) $D^bK^{b-/-}$ mice without (i,iii) and with (ii,iv) pre-training, with states of weak synaptic strength at the top and strong states underneath.

$D^bK^{b-/-}$ mice, as the equilibrium distribution is not as heavily concentrated at the end (see [Figure 12cii](#)).

This model shares both features of the [serial model](#). First, the effect of initial saturation bias is amplified by the exponential decay of transition probabilities away from the middle. Second, it has the metaplastic effect where repeated potentiation makes future depression harder, also due to the exponential decay of transition probabilities.

2.6 Non-uniform multistate model

The results of simulations of the non-uniform multistate model can be seen in [Figure 13](#). It is difficult to study this model analytically. However, the numerical results can help us understand it qualitatively.

First, we see that the $D^bK^{b-/-}$ mice are slower than wild-type without pre-training, as seen experimentally. This seems to be because the enhanced depression results in a greater fraction of synapses begin in states of weaker synaptic weight (see [Figure 13cii](#)) where the depressing transitions have lower probability (see [Figure 3](#)).

However, gain-decrease pre-training will push synapses towards the states of stronger synaptic weight. The wild-type will be pushed further than the $D^bK^{b-/-}$ mice, as the latter started further to the weaker side as explained above (compare [Figure 13ci](#) and [ii](#)). As the depressing transitions have lower probability for the strongest states (see [Figure 3](#)), this, in addition to the enhanced depression of the $D^bK^{b-/-}$ mice, will result in the $D^bK^{b-/-}$ mice learning faster than wild-type, as seen experimentally.

When comparing learning with and without gain-decrease pretraining, there are two effects to consider. First, the pushing synapses towards the states of stronger synaptic weight, resulting in more synapses being available for depression, speeding up learning. Second, it will also place synapses in states where transitions have lower probability, slowing down learning. The second effect will be weaker in the $D^bK^{b-/-}$ mice than in wild-type, as they started further to the weaker side as explained above. This means that, for appropriate parameter choices, gain-decrease pretraining can speed up learning in the $D^bK^{b-/-}$ mice, but also slow down learning in wild-type, as seen experimentally.

Like the [cascade model](#), this model also shares both features of the [serial model](#). First, the effect of initial saturation bias is amplified by the exponential decay of transition probabilities away from the middle. Second, it has the metaplastic effect where repeated potentiation makes future depression harder, also due to the exponential decay of transition probabilities.
